# Introduction to Reinforcement Learning 4/10

Jean Martinet

MSc DSAI

2024 - 2025

#### Programme

- Introduction
  - Course 1 : Introduction to Reinforcement Learning (RL)
- Part I on tabular methods
  - Course 2: Markov Decision Processes
  - Course 3 : Dynamic programming in RL
  - Course 4 : Temporal difference 1/2 (Q-learning)
  - Course 5 : Temporal difference 2/2 (SARSA)
- Part II on approximate methods
  - Course 6 : Value function approximation
  - Course 7 : Eligibility traces
  - Course 8 : Policy gradient 1/2 (REINFORCE)
  - Course 9 : Policy gradient 2/2 (actor-critic methods)
  - Course 10 : Projects presentation session

## Reminder: think of a project topic

#### Choose from :

- Public presentation of articles/advanced topics/applications
  - Conference paper or book chapter
  - Advanced theme (e.g. actor-critic, eligibility trace, etc.)
  - Application domain (e.g. temperature control, revenue management, etc.)
- Deepening or exploration project
  - Subject to be chosen/defined and validated
- Choice to be validated... today
- Expected result :
  - Short 2-page max PDF report
  - Code (ipynb / py / git)
  - Short 10-min presentation during last / before last session

#### About the project

- Double objective
  - Dig deeper in a specific subject (discussed or not during the lectures)
  - Share your insights with other students (in a teacher mode)
- A bit hard to choose early, before having reviewed all topics
- If you can define what is the environment, the reward, the agent, and the actions, it is a good start
- Stay small, at least for a first version, then make it more complex if you have time
- An experimental contribution is needed
  - E.g. compare two algorithms
  - E.g. start from an existing approach, and monitor changes when parameters vary
- The project needs be ORIGINAL
  - You need an original contribution of your own
  - Make sure your project is different from what can be found online
- IMPORTANT: if you decide to use an existing work, it is MANDATORY to cite the source, and you need to state what your contribution is

## Today's menu

- Monte Carlo methods
- Dynamic programming vs Temporal difference
- On-policy vs off-policy learning
- Exploration vs exploitation
- Optimal policy approximation with Q-learning

#### Monte Carlo methods

- MC does not assume a complete knowledge of the environment
  - MC methods require only experience, contrary to DP
  - A model is required
  - Obtain optimal behaviour without any prior information about environment dynamics
    - It is sometimes easier to generate transitions than to obtain complete probability distributions in explicit forms
- The method is based on averaging sample returns
  - Strong assumption: episodic tasks only to insure that well defined returns are available
  - Only after episode completion, value estimates and policies are changed – not step-by-step updates

#### MC prediction

- Prediction means: "evaluate policies"
- Simple average of returns observed after visits to each state
- Converges to the true expected values when the number of visits to s
  goes to infinity
- Two-versions : first-visit and every-visit

First-visit MC prediction, for estimating  $V \approx v_{\pi}$ 

 $V(S_t) \leftarrow \text{average}(Returns(S_t))$ 

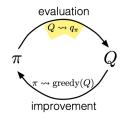

```
Input: a policy \pi to be evaluated  
Initialize: V(s) \in \mathbb{R}, \text{ arbitrarily, for all } s \in \mathcal{S} \\ Returns(s) \leftarrow \text{ an empty list, for all } s \in \mathcal{S}   
Loop forever (for each episode): Generate an episode following \pi\colon S_0, A_0, R_1, S_1, A_1, R_2, \ldots, S_{T-1}, A_{T-1}, R_T  
G \leftarrow 0  
Loop for each step of episode, t = T-1, T-2, \ldots, 0:  
G \leftarrow \gamma G + R_{t+1}  
Unless S_t appears in S_0, S_1, \ldots, S_{t-1}:  
Append G to Returns(S_t)
```

#### Evaluation of action values

- With a model, state values alone are sufficient to determine a policy
  - Just select the action that leads to the best  $(s_{t+1}, r_{t+1})$  as in DP
- When a model is not available, we need to explicitly evaluate the value of actions
  - Estimate  $Q^{\pi}(s, a)$  similarly, except that we now deal with (s, a) visits
- However, many (s, a) pairs may never be visited if  $\pi$  is deterministic
  - Option to force the episode to start with all possible (s, a)
  - This is the exploring starts assumption in simulation not real world

#### MC control

- Control means : "approximate optimal policies"
- Generalised Policy iteration
  - Greedy policy with the same pattern as DP with  $\pi(s) \doteq \arg\max_a Q^{\pi}(s,a)$

$$\pi_0 \xrightarrow{\to} q_{\pi_0} \xrightarrow{\mathrm{I}} \pi_1 \xrightarrow{\mathrm{E}} q_{\pi_1} \xrightarrow{\mathrm{I}} \pi_2 \xrightarrow{\mathrm{E}} \cdots \xrightarrow{\mathrm{I}} \pi_* \xrightarrow{\mathrm{E}} q_*$$

#### Temporal difference

Simplest TD update

$$V(s_t) \leftarrow V(s_t) + \alpha[r_{t+1} + \gamma V(s_{t+1}) - V(s_t)]$$

- The amount in brackets is an error measuring the difference between
  - the estimated value of  $S_t$  and
  - the better estimate  $r_{t+1} + \gamma V(s_{t+1}) V(s_t)$
- This quantity is called the *TD error*

$$\delta_t \doteq r_{t+1} + \gamma V(s_{t+1}) - V(s_t)$$

## Tabular TD(0)

#### Tabular TD(0) for estimating $v_{\pi}$

```
Input: the policy \pi to be evaluated Algorithm parameter: step size \alpha \in (0,1] Initialize V(s), for all s \in \mathcal{S}^+, arbitrarily except that V(terminal) = 0 Loop for each episode: Initialize S Loop for each step of episode: A \leftarrow action given by \pi for S Take action A, observe R, S' V(S) \leftarrow V(S) + \alpha \big[ R + \gamma V(S') - V(S) \big] S \leftarrow S' until S is terminal
```

#### Dynamic programming vs Time difference

- In DP, we assumed a complete knowledge of the environment (MDP)
  - We computed value functions
  - Now with TD, we learn them
- We require only experience
  - Actual : no prior knowledge of environment is required
  - Simulated : a model is required to generate sample transitions
  - (it is easier to get sample transitions than the complete distribution)
- Everything else remains similar

#### On-policy vs off-policy

- Our agent learns action values relying on our current policy estimate
  - But it needs to behave non-optimally to explore all actions
- (and find optimal actions)
- We can use and distinguish two policies
  - The policy that we learn and becomes optimal (target  $\pi$ )
  - The exploratory policy that generates behaviour (behaviour  $\pi$ )
- This is off-policy learning
- On the contrary, *on-policy* methods use a single policy

## Greedy actions vs exploratory actions

 Simplest action selection rule : select one of the actions with the highest estimated value

$$A_t \doteq \arg\max_a Q^{\pi}(s,a)$$

- Greedy action selection exploit current knowledge to maximise immediate reward
- Alternative :
  - Behave greedily most of the time
  - Sometimes, with probability  $\epsilon$ , randomly pick another action (exploratory move)
- This is the  $\epsilon$ -greedy method

#### $\epsilon$ -greedy action selection

- ullet Trade-off between exploration and exploitation using  $\epsilon$  value
- ullet starts at 1 (only exploration) then decreases (more exploitation)
- Choose a random number r between 0 and 1 (uniform distribution) :
  - if  $r < \epsilon$ : choose a random action (exploration)
  - if  $r \ge \epsilon$  : choose the best action = maximising Q value (exploitation)

#### Q-learning algorithm

- Here again,  $\pi$  evaluation (prediction) and  $\pi$  improvement towards  $\pi^*$  (control)
- Q-learning is an off-policy TD algorithm

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha [r_{t+1} + \gamma \max_{a} Q(s_{t+1}, a) - Q(s_t, a_t)]$$

- ullet Iteratively updates action-value using  $\delta_t$
- ullet  $\alpha$  is the learning rate
- Build a Q-table of size  $|S| \times |A|$ , initial values are 0s
- Iterate episodes (a few hundreds)
  - Iterate steps in each episode
    - Select the best action a in state s, use the reward to update Q
    - Episode terminates when agent reaches a terminal state (or max iteration)

# Today's lab (graded, duration 1h30)

- 1. Consider a 1D grid with :
  - ullet one goal location (positive reward, e.g. +1)
  - one trap location (negative reward, e.g. -1)
  - a fixed move cost (e.g. -0.01)
  - deterministic actions (probability to go left when trying left is 1)
- Implement Q-learning from the equation, with  $\epsilon$ -greedy
- Run your algorithm to determine the best policy, check it
- 2. Extend to the 2D grid of the classical toy example (lecture 1)
- 3. Optional : Visualise results with plots for several values of  $\gamma$ ,  $\alpha$ , and  $\epsilon$  (brings bonus!)
- (Note: use Python and numpy only gym next week)
- Submit your solution after 90 min
